## Abstract

Given a digraph  $D = (V, A)$  and a set of  $\kappa$  pairs of vertices in  $V$ , we are interested in finding, for each pair  $(x_i, y_i)$ , a directed path connecting  $x_i$  to  $y_i$  such that the set of  $\kappa$  paths so found is arc-disjoint. For arbitrary graphs the problem is  $\mathcal{NP}$ -complete, even for  $\kappa = 2$ .

We present a polynomial time randomized algorithm for finding arc-disjoint paths in an  $r$ -regular expander digraph  $D$ . We show that if  $D$  has sufficiently strong expansion properties and the degree  $r$  is sufficiently large then *all* sets of  $\kappa = \Omega(n/\log n)$  pairs of vertices can be joined. This is within a constant factor of best possible.

## 1 Introduction

Given a (graph) digraph  $D = (V, A)$  with  $n$  vertices and a set of  $\kappa$  pairs of vertices in  $V$ , we are interested in finding, for each pair  $(x_i, y_i)$ , a (undirected) directed path connecting  $x_i$  to  $y_i$ , such that the set of  $\kappa$  paths so found is (edge) arc-disjoint. This is a classical problem in graph theory. See Frank [7] for a survey and Chapter 9.2 of the recent book on digraphs by Bang-Jensen and Gutin [2].

For undirected graphs, the related decision problem is in  $\mathcal{P}$  for fixed  $\kappa$  – Robertson and Seymour [22], but is  $\mathcal{NP}$ -complete if  $\kappa$  is part of the input. For digraphs the situation is seemingly much worse. Fortune, Hopcroft and Wylie [6] showed that the related decision problem is  $\mathcal{NP}$ -complete, even when  $\kappa = 2$ .

For undirected graphs there have been positive results in the case of expanders. Peleg and Upfal [21] presented a polynomial time algorithm for the case where  $D$  is a (sufficiently strong) bounded degree expander graph and  $\kappa \leq n^\epsilon$  for a small constant  $\epsilon$  that depends on the expansion property of the graph. This result has been improved and extended by

Broder, Frieze, and Upfal [4, 5], Frieze [8, 9], Leighton and Rao [17] and Leighton, Rao and Srinivasan [18, 19]. In particular Frieze [9] showed that if  $D$  has sufficiently strong *edge* expansion properties and  $r$  is sufficiently large then *all* sets of  $\kappa = \Omega(n/\log n)$  pairs of vertices can be joined. This is within a constant factor of a simple upper bound. The purpose of this paper is to extend this result to digraphs.

In this paper we discuss  $r$ -regular digraphs. A digraph  $D$  is  $r$ -regular if every vertex has in-degree and out-degree  $r$ . Let  $d_\mu$  be the median distance between pairs of vertices in the digraph  $D$  which has  $m$  arcs. Clearly, there exists a collection of  $O(m/d_\mu)$  pairs of vertices that cannot be connected by arc-disjoint paths because such a collection of paths would require more arcs than all the arcs available. In the case of an  $r$ -regular expander, this absolute upper bound on  $\kappa$  is  $O(n/\log n)$  (assuming  $r$  is independent of  $n$ ). We show that if  $D$  has sufficiently strong *arc* expansion properties and  $r$  is sufficiently large then *all* sets of  $\kappa = \Omega(n/\log n)$  pairs of vertices can be joined. This therefore, is within a constant factor of the optimum. The precise definition of “sufficiently strong” is given after the theorem.

**Theorem 1** *Let  $D = (V, A)$  be an  $n$ -vertex,  $r$ -regular digraph. Suppose that  $D$  is a sufficiently strong arc expander. Then there exist  $\epsilon_1, \epsilon_2 > 0$  such that  $D$  has the following property: For all sets of pairs of vertices  $\{(x_i, y_i) \mid i = 1, \dots, \kappa\}$  satisfying*

- (i)  $\kappa = \lceil \epsilon_1 r n / \log n \rceil$ , and
- (ii) For each vertex  $v$ ,  $|\{i : x_i = v\}|, |\{i : y_i = v\}| \leq \epsilon_2 r$

*there exist arc-disjoint paths in  $D$ , each of length  $O(\log n)$ , joining  $x_i$  to  $y_i$ , for each  $i = 1, 2, \dots, \kappa$ . Furthermore, there is a polynomial time randomized algorithm for constructing these paths. The constants  $\epsilon_1, \epsilon_2$  depend only on certain expansion parameters  $\alpha, \beta, \gamma$  defined below. They do not depend on  $n$  or  $r$ . (For example conditions (2) with  $\epsilon = \alpha$ , (3), (9) and (12) suffice).*

**Remark 1** *The algorithm is similar to the algorithm of [9]. The difficulty in moving from graphs to digraphs has been with that part of the algorithm for graphs which was based on the rapid mixing of a random walk on expanders. Random walks on digraphs are not necessarily time reversible and the steady state can be hard to determine. We therefore abandoned this approach and replaced it with a different random choice of path (in part, this random choice for digraphs uses the multicommodity flow results of Leighton and Rao [16]).*

*It will be observed that this new algorithm can substitute for that given in [9].*

**Remark 2** *If  $D$  has sufficiently strong vertex expansion properties then we can take  $\kappa = \lceil \epsilon_1 r n / \log_r n \rceil$  – see Remark 4 below.*

**Remark 3** *It is perhaps worth remarking that regularity is not crucial to the result. One can easily extend the results to digraphs where in- and out-degrees are constrained to be in the interval  $[r, ar]$  where  $a \geq 1$  is an absolute constant. All we need is for  $r$  to be sufficiently large. The really crucial property is strong expansion.*

## 1.1 Preliminaries

In this section we state the definitions for the expanders we work with here, make some preliminary observations about such expanders, and make precise the notion of ‘sufficiently strong’ expansion needed for Theorem 1. We begin with some notational conventions.

Let  $D = (V, A)$  be a digraph and let  $n = |V|$ . For  $S, T \subseteq V$  let  $A_D^+(S, T)$  be the set of arcs with tail in  $S$  and head in  $T$ ; that is,

$$A^+(S, T) = A_D^+(S, T) = \{(u, v) \in A \mid u \in S, v \in T\} \quad \text{and} \quad d^+(S, T) = |A^+(S, T)|.$$

We define  $A^-(S, T)$  similarly (i.e.  $A^-(S, T) = A^+(T, S)$ ). We set

$$A^+(S) = \{(u, v) \in A \mid u \in S, v \notin S\} \quad \text{and} \quad d^+(S) = |A^+(S)|.$$

So, for example, we have  $A^+(S) = A^+(S, V \setminus S)$ . We define  $A^-(S)$  and  $d^-(S)$  analogously. Throughout the paper, when  $\star$  is used as a subscript or superscript, it stands for  $+$  or  $-$ . We abbreviate  $A^*(\{v\}, T)$  to  $A^*(v, T)$ . Thus, for  $v \in V$ ,  $d_D^+(v)$  and  $d_D^-(v)$  denote the out-degree and in-degree of  $v$  in  $D$ .

We now have the notation necessary to introduce expansion. We define expanders in terms of arc expansion (a weaker property than vertex expansion). For  $S \subseteq V$  let  $\Phi_S^* = d^*(S)/|S|$ . The (arc-)expansion  $\Phi = \Phi(D)$  of  $D$  is defined by

$$\Phi = \min_{\substack{S \subseteq V \\ |S| \leq n/2}} \min\{\Phi_S^+, \Phi_S^-\}.$$

A digraph  $D = (V, A)$  is a  $\theta$ -expander, if for every set  $S \subseteq V$ ,  $|S| \leq n/2$ , we have  $d^*(S) \geq \theta|S|$ ; in other words,  $D$  is a  $\theta$ -expander if  $\Phi(D) \geq \theta$ . An  $r$ -regular digraph  $D = (V, A)$  is called an  $(\alpha, \beta, \gamma)$ -expander if for every set  $S \subseteq V$

$$d^*(S) \geq \begin{cases} (1 - \alpha)r|S| & \text{if } |S| \leq \gamma n \\ \beta r|S| & \text{if } \gamma n < |S| \leq n/2 \end{cases}$$

We naturally assume that  $\beta < 1 - \alpha$ . By ‘sufficiently strong’ in Theorem 1, we mean that  $\beta, \gamma$  are arbitrary and  $\alpha$  is sufficiently small; in particular, we assume that conditions (2) with  $\epsilon = \alpha$ , (3), (9) and (12) hold. We also assume throughout that  $r$  and  $n$  are sufficiently large (but  $r$  is *not* a function of  $n$ ). We have made no real attempt to optimize constants. Such digraphs exist; in particular, random regular digraphs are usually  $(\alpha, \beta, \gamma)$ -expanders. (See discussion in [4] for the corresponding notion in undirected graphs.)

We conclude this section with some preliminary observations about expanders. Since  $|A^*(S, S)| + d^*(S) = r|S|$  we see that, putting  $in(S) = |A^+(S, S)| = |A^-(S, S)|$ , in an  $(\alpha, \beta, \gamma)$ -expander

$$in(S) \leq \alpha r|S| \quad \text{when } |S| \leq \gamma n. \quad (1)$$

For a digraph  $\Delta = (V', A')$  and a set  $S \subseteq V'$  we define its out-neighbor set  $N_\Delta^+(S)$ , as

$$N_\Delta^+(S) = \{w \notin S : \exists v \in S \text{ such that } (v, w) \in A'\}.$$

Similarly, the in-neighbor set of  $S$ ,  $N_{\Delta}^{-}(S)$  is given by

$$N_{\Delta}^{-}(S) = \{w \notin S : \exists v \in S \text{ such that } (w, v) \in A'\}.$$

**Lemma 1** *Suppose that  $D = (V, A)$  is an  $(\alpha, \beta, \gamma)$ -expander and that  $D' = (V', A')$  is a sub-digraph of  $D$  of expansion at least  $\theta r$  where  $\theta > \alpha$ . Suppose  $S \subseteq V'$ . If  $|S| \leq \frac{\gamma\alpha}{\theta}n$  then*

$$|N_{D'}^*(S)| \geq \frac{\theta - \alpha}{\alpha}|S|.$$

**Proof:** Suppose that  $|S| \leq \frac{\gamma\alpha}{\theta}n$  and  $T = N_{D'}^*(S)$  satisfies  $|T| < \frac{\theta - \alpha}{\alpha}|S|$ . Then

$$|S \cup T| < \left(1 + \frac{\theta - \alpha}{\alpha}\right) |S| = \frac{\theta}{\alpha}|S| \leq \gamma n.$$

But,  $S \cup T$  contains at least

$$\theta r |S| > \theta r \left(1 + \frac{\theta - \alpha}{\alpha}\right)^{-1} |S \cup T| = \alpha r |S \cup T|$$

arcs, which contradicts (1).  $\square$

## 2 The algorithm

The input to our algorithm is a sufficiently strong  $(\alpha, \beta, \gamma)$ -expander digraph  $D$  and a set of pairs of vertices  $\{(x_i, y_i) \mid i = 1, \dots, \kappa\}$  satisfying the premises of Theorem 1. The output is a set of  $\kappa$  arc-disjoint paths,  $P_1, \dots, P_{\kappa}$  such that  $P_i$  connects  $x_i$  to  $y_i$ .

The algorithm has three phases. We begin in Phase 0 by splitting our graph into 13 arc-disjoint expanders  $D_i = (V, A_i)$ ,  $1 \leq i \leq 13$ . These graphs will be used for various purposes in Phases 1 and 2, and each path we construct will be a union of paths in the  $D_i$ 's. Phase 1 consists mainly of applications of GENPATHS, an algorithm that uses the expander property to naively connect pairs of vertices with paths of length  $O(\log n)$  one at a time, deleting the arcs from a path as soon as it is used. Of course, this deletion of arcs may quickly destroy the expander property. To compensate for this problem, GENPATHS 'shrinks' the expanders in which it finds paths. The real work of GENPATHS is in keeping as many vertices as possible 'connected' to these shrinking expanders. Those pairs of vertices that are not connected with paths in Phase 1 (i.e. those pairs that contain a vertex whose connection with one of the 'shrinking expanders' is lost) are handled in Phase 2. There are  $O\left(\frac{n}{\log^4 n}\right)$  such pairs. Loosely speaking, Phase 2 uses the multicommodity flow algorithm of Leighton and Rao to give a distribution on paths connecting the remaining pairs such that **whp** paths chosen at random with respect to this distribution are arc disjoint.

## 2.1 Phase 0.

We need an algorithm for splitting a  $(\alpha, \beta, \gamma)$ -expander digraph into 13 expander digraphs. Algorithms for splitting undirected graphs are given in [4] or [10]. They are easily adapted to digraphs and we outline an adaptation of the algorithm of [10] in Appendix A. In the appendix we prove:

**Theorem 2** *Suppose we have*

$$\frac{r}{\log r} \geq 91\epsilon^{-2} \text{ and } \beta \geq 65\epsilon^{-2}r^{-1} \log 2er \quad (2)$$

*and that  $G$  is an  $r$ -regular  $(\alpha, \beta, \gamma)$ -expander,  $r$  constant. Then there is a randomized polynomial time algorithm which with probability at least  $1 - \delta$  constructs  $A_1, A_2, \dots, A_{13}$  such that the arc-expansion  $\Phi_i$  of  $D_i = (V, A_i)$  satisfies*

$$\Phi_i \geq (1 - \epsilon) \frac{\Phi}{13} - (\alpha + 2\epsilon)r,$$

*for  $i = 1, 2, \dots, 13$ .*

This theorem is only useful if  $\Phi$  is at least a constant multiple of  $r$  and  $\alpha$  is sufficiently small. This is the case discussed in this paper. The algorithm runs in  $O(n^2 \ln n \log \delta^{-1})$  expected time. There is not enough time to verify that the algorithm succeeds. Instead, we simply assume it has and repeat the split if we fail to find the required paths.

We apply the algorithm of Theorem 2 with  $\alpha = \epsilon$  and assume that

$$\beta > 156\alpha. \quad (3)$$

Setting

$$\beta_0 = \frac{\beta}{13} - 4\alpha > 8\alpha > 0, \quad (4)$$

each  $D_i$  satisfies

$$\Phi_i = \Phi(D_i) \geq \beta_0 r, \quad \text{and} \quad (5)$$

$$\beta_0 r \leq d_i^*(v) < r, \quad \text{for all } v \in V. \quad (6)$$

## 2.2 Phase 1.

Phase 1 uses expanders  $D_1$  through  $D_6$ . The centerpiece of Phase 1 is the algorithm GENPATHS that connects a large collection of *random* pairs of vertices in an expander with arc-disjoint paths. Since the pairs  $x_i, y_i$  are arbitrary, GENPATHS cannot be applied to them directly; we must reduce the problem of connecting the  $x_i$ 's to the  $y_i$ 's to the problem of connecting random pairs.

In order to produce random pairs we introduce three random sets of  $\kappa$  vertices:  $\tilde{X}$ ,  $\tilde{Y}$  and  $Z$ . In the Initialization step of Phase 1, a network-flow technique is used to find a collection

of arc-disjoint paths  $\mathcal{P}^1 = \{P_i^1 : i = 1, \dots, \kappa\}$  from  $X = \{x_1, \dots, x_\kappa\}$  to  $\tilde{X}$  in expander  $D_1$  such that the path  $P_i^1$  starts at  $x_i$  for  $i = 1, \dots, \kappa$ . It is important to note that we have no control over which element of  $\tilde{X}$  is at the end of the path  $P_i^1$  (but there will be one path ending at  $x$  for each  $x \in \tilde{X}$ ). This network-flow technique is also used in the Initialization step of Phase 1 to find a collection of arc-disjoint paths  $\mathcal{P}^6 = \{P_i^6 : i = 1, \dots, \kappa\}$  from  $\tilde{Y}$  to  $Y = \{y_1, \dots, y_\kappa\}$  in  $D_6$  such that the endpoint of the path  $P_i^6$  is  $y_i$ . After the Initialization step, we take a random ordering of  $\tilde{X}$ :  $\tilde{X} = \{\tilde{x}_1, \dots, \tilde{x}_\kappa\}$ . Furthermore, we order  $\tilde{Y}$  so as to respect the pairing of  $\tilde{X}$  and  $\tilde{Y}$  that is inherited from the collections  $\mathcal{P}^1$  and  $\mathcal{P}^6$ ; that is, we set  $\tilde{Y} = \{\tilde{y}_1, \dots, \tilde{y}_\kappa\}$  so that if the endpoint of  $P_i^1$  is  $\tilde{x}_j$  then  $\tilde{y}_j$  is the starting point of  $P_i^6$ . Thus, it remains to find a collection of arc-disjoint paths connecting the pairs  $\{(\tilde{x}_i, \tilde{y}_i) : i = 1, \dots, \kappa\}$ . Unfortunately this sequence of pairs of vertices is *not* truly random. This is a consequence of the fact that the pairing between  $\tilde{X}$  and  $\tilde{Y}$  is determined by a deterministic process (i.e. knowledge of some of the *pairs* from this collection may bias the distribution on the unknown pairs). We overcome this problem by introducing the third random set  $Z = \{z_1, \dots, z_\kappa\}$ . The sequences  $\{(\tilde{x}_i, z_i) : i = 1, \dots, \kappa\}$  and  $\{(z_i, \tilde{y}_i) : i = 1, \dots, \kappa\}$  are perfectly random sequences of pairs of vertices (so long as we view them separately). It remains to connect these two sequences of pairs of vertices with arc-disjoint paths. This is the work of the algorithm GENPATHS.

The input to GENPATHS is a pair of expanders,  $D_a$  and  $D_b$ , and a collection of pairs of vertices  $\{(v_i, u_i) : i = 1, \dots, \kappa\}$  that is generated uniformly at random. The output of GENPATHS is a collection of arc-disjoint paths from  $v_i$  to  $u_i$  for  $i = 1, \dots, \kappa$  that use only the arcs from  $D_a$  and  $D_b$ . We apply GENPATHS twice. For the first application we set  $D_a = D_2$ ,  $D_b = D_3$  and  $\{(v_i, u_i) : i = 1, \dots, \kappa\} = \{(\tilde{x}_i, z_i) : i = 1, \dots, \kappa\}$ . In the second application we set  $D_a = D_4$ ,  $D_b = D_5$  and  $\{(v_i, u_i) : i = 1, \dots, \kappa\} = \{(z_i, \tilde{y}_i) : i = 1, \dots, \kappa\}$ . Now, the expander  $D_a$  is used to connect the  $v_i$ 's to the  $u_i$ 's with *short* paths one at a time. In order to be sure that such paths exist we must be working with an expander. Therefore we delete some vertices in the course of the algorithm; in other words, this expander shrinks as the algorithm progresses.  $D_b$  is used to keep as many vertices as possible connected to the 'shrinking expander' contained in  $D_a$ . We should note that these connections also require that  $D_b$  be an expander. So,  $D_b$  also 'shrinks' in the course of the algorithm. The subroutines REMOVE and CONNECTBACK are used by GENPATHS.

### 2.2.1 Initialization

Let  $\tilde{X}, \tilde{Y}$  be two randomly chosen  $\kappa$ -subsets of  $V$ . We begin by replacing the problem of finding paths from  $x_i$  to  $y_i$  by that of finding paths from  $a_i$  to  $b_i$ , where  $a_i \in \tilde{X}$  and  $b_i \in \tilde{Y}$ . Let  $X$  denote the set  $\{x_1, x_2, \dots, x_\kappa\}$  and  $Y = \{y_1, y_2, \dots, y_\kappa\}$ . We connect  $X$  to  $\tilde{X}$  via arc-disjoint paths in the digraph  $D_1$  using a network flow. We construct our network as follows

- Each directed arc of  $D_1$  gets capacity 1.
- Each  $v \in V$  becomes a source of capacity  $|\{i : x_i = v\}|$  and each member of  $\tilde{X}$  becomes a sink of capacity 1.

Then we find a flow from  $X$  to  $\tilde{X}$  that satisfies all demands. We can find such a maximum flow with integer values and this decomposes naturally into  $|X|$  arc-disjoint paths (together perhaps with some cycles). We connect  $\tilde{Y}$  to  $Y$  by arc-disjoint paths in a similar manner using  $D_6$

We now have a collection of arc-disjoint paths  $\mathcal{P}^1 = \{P_i^1 : i = 1, \dots, \kappa\}$  such that the starting point of  $P_i^1$  is  $x_i$  for  $i = 1, \dots, \kappa$  and each member of  $\tilde{X}$  is the endpoint of exactly one path from  $\mathcal{P}^1$ . Furthermore, we have a collection of arc-disjoint paths  $\mathcal{P}^6 = \{P_i^6 : i = 1, \dots, \kappa\}$  such that each member of  $\tilde{Y}$  is the starting point of exactly one path from  $\mathcal{P}^6$  and the end-point of path  $P_i^6$  is  $y_i$  for  $i = 1, \dots, \kappa$ .

### 2.2.2 Algorithm GENPATHS.

The aim of GENPATHS is to join  $v_i$  and  $u_i$  for  $i = 1, 2, \dots, \kappa$  by a *short* (i.e. of length  $O(\log n)$ ) path in  $D_a$ . After constructing a path, we remove its arcs. It is important to ensure that short paths exist. Of course, this would not be a problem if we could ensure that  $D_a$  remains an expander throughout. We have to be satisfied with identifying a *dynamically changing large* subgraph  $\Delta_a = (V_a, F_a)$  of  $D_a$  which is an expander. Initially  $\Delta_a = D_a$ , and  $V_a$  loses vertices as GENPATHS progresses. We ensure that  $\Delta_a$  remains an expander by keeping the degrees of vertices in the  $\Delta_a$  close to their degree in  $D_a$ . This may involve deleting some (low degree) vertices after the construction of a path. We use the routine REMOVE to do this.

If the proposed start vertex  $v$  of a walk on  $\Delta_a$  does not lie in  $V_a$  then we try to *connect it back* to  $V_a$  by a path in  $D_b$ . The terminal endpoint of this walk is denoted by  $v'$ . We use a subroutine CONNECTBACK for this purpose. Similarly, the proposed end vertex  $u$  might not lie in  $V_a$ . In this case we use CONNECTBACK to find a path from some  $u' \in V_a$  to  $u$  in  $D_b$ . We do not expect to succeed all the time and our failures are kept in a set  $L$  for treatment in Phase 2. The arcs in the paths generated by CONNECTBACK are deleted from  $D_b$ . Since CONNECTBACK requires that  $D_b$  is an expander we will also be working with a second ‘shrinking expander’  $\Delta_b = (V_b, F_b)$  contained in  $D_b$ . This shrinking expander will also be maintained by use of the subroutine REMOVE.

In the end, the path from  $v_i$  to  $u_i$  will be a concatenation of up to three separate paths. There will always be a path  $Q_i$  from  $D_a$ , and there may also be a short walk (or walks) from  $D_b$  provided by CONNECTBACK (these are denoted  $W_i^{CB \rightarrow}$  and  $W_i^{CB \leftarrow}$ , respectively).

1. **Algorithm** GENPATHS
2. **begin**
3.      $\Delta_t \leftarrow D_t, t = a, b.$
4.     **for**  $i = 1$  **to**  $\kappa$  **do**
5.         **Execute** REMOVE( $\Delta_a$ )
6.         **Execute** CONNECTBACK( $V_a, v_i, \rightarrow, v'_i, i, W_i^{CB\rightarrow}$ )
7.         **Execute** CONNECTBACK( $V_a, u_i, \leftarrow, u'_i, i, W_i^{CB\leftarrow}$ )
8.         **if**  $i \notin L$  **then**
9.             Construct a shortest path  $Q_i$  from  $v'_i$  to  $u'_i$  in  $\Delta_a$ .
10.             $P_i \leftarrow (W_i^{CB\rightarrow}, Q_i, W_i^{CB\leftarrow})$
11.             $\Delta_a \leftarrow \Delta_a \setminus E(P_i)$
12.         **fi**
13.     **od**
14. **end** GENPATHS

### 2.2.3 Subroutine REMOVE

The purpose of REMOVE is to delete vertices which might prevent a digraph from being an expander. In the course of GENPATHS we apply REMOVE to  $\Delta_a$  and  $\Delta_b$ . In words, this simple algorithm iteratively removes those vertices whose in/out degree is less than the original in/out degree minus  $\beta_0 r/2$ . To be precise, at the end of the algorithm we have a graph  $\Delta_t = (V_t, F_t)$  where  $t \in \{a, b\}$  such that

$$v \in V_t \text{ implies } d_{\Delta_t}^*(v) \geq d_{D_t}^*(v) - \beta_0 r/2 \geq \beta_0 r/2. \quad (7)$$

The final inequality in (7) follows from (6). It follows immediately from (7) that for  $S \subseteq V_t$  we have

$$d_{\Delta_t}^*(S) \geq d_{D_t}^*(S) - \beta_0 r|S|/2 \geq (\Phi_t - \beta_0 r/2)|S|.$$

This implies that, provided neither  $V_a$  nor  $V_b$  become empty (an issue which we take up in the next section), both  $\Delta_a$  and  $\Delta_b$  are expanders throughout Phase 1:

$$\Phi_{\Delta_t} \geq \Phi_t - \beta_0 r/2 \geq \beta_0 r/2 \quad \text{for } t = a, b. \quad (8)$$

1. **Algorithm REMOVE**( $\Delta_t$ )
2. **begin**
3.    $B \leftarrow \{v \in V_t : d_{\Delta_t}^+(v) < d_{D_t}^+(v) - \beta_0 r/2 \text{ or } d_{\Delta_t}^-(v) < d_{D_t}^-(v) - \beta_0 r/2\}$ .
4.   **if**  $B \neq \emptyset$  **then**
5.      $A \leftarrow V_t \setminus B$
6.      $d \leftarrow \max\{\max\{d_{D_t}^+(v) - d_{\Delta_t}^+(v, A), d_{D_t}^-(v) - d_{\Delta_t}^-(v, A)\} : v \in A\}$ .
7.     **while**  $d > \beta_0 r/2$  **do**
8.        $C \leftarrow \{w \in A : \max\{d_{D_t}^+(w) - d_{\Delta_t}^+(w, A), d_{D_t}^-(w) - d_{\Delta_t}^-(w, A)\} \geq \beta_0 r/2\}$
9.        $B \leftarrow B \cup C$
10.       $A \leftarrow A \setminus C$
11.       $d \leftarrow \max\{\max\{d_{D_t}^+(v) - d_{\Delta_t}^+(v, A), d_{D_t}^-(v) - d_{\Delta_t}^-(v, A)\} : v \in A\}$ .

#### 2.2.4 Subroutine CONNECTBACK.

The purpose of **CONNECTBACK** is to connect a vertex  $z$  to  $V_a$  by means of a short walk in  $D_b$ . The direction of this walk is determined by the input  $\text{dir}$ . If  $\text{dir} = \rightarrow$  then a path from  $z$  to  $V_a$  is required, and if  $\text{dir} = \leftarrow$  then a path from  $V_a$  to  $z$  is needed. If  $z \in V_a$  already then **CONNECTBACK** does nothing but relabel  $z$  as  $z'$ . Since  $|V \setminus V_a|$  can be of order  $n$  (this is discussed below), we must maintain the expander property of  $\Delta_b$  in order to find short connecting paths. Thus we apply **REMOVE** to  $\Delta_b$  in the course of **CONNECTBACK**. Now, those pairs that contain a vertex that lies in  $V \setminus (V_a \cup V_b)$  are passed to Phase 2 in the set  $L$ . Thus, the long term success of **CONNECTBACK** hinges on keeping  $V \setminus (V_a \cup V_b)$  small. In fact, this can be viewed as the key point in all of **GENPATHS**.

We keep  $V_b$  large by ensuring that the paths we use in  $\Delta_b$  are spread out; in other words, we avoid using too many paths through any one vertex. This is achieved **whp**; recall that the pairs of vertices  $\{(v_i, u_i) : i = 1, \dots, \kappa\}$  that are the input to **GENPATHS** are assumed to be generated uniformly at random. When a path is needed (i.e when  $z \notin V_a$ ) **CONNECTBACK** constructs a collection  $\mathcal{W}^{\text{dir}}$  of walks in  $\Delta_b$ . This collection has the following properties.

1. If  $\text{dir} = \rightarrow$  then every walk in  $\mathcal{W}^{\text{dir}} = \mathcal{W}^{\rightarrow}$  is a walk from a distinct vertex in  $V_b \setminus V_a$  to  $V_a$ .
2. If  $\text{dir} = \leftarrow$  then every walk in  $\mathcal{W}^{\text{dir}} = \mathcal{W}^{\leftarrow}$  is a walk from  $V_a$  to a distinct vertex in  $V_b \setminus V_a$ .
3. No path in  $\mathcal{W}^{\text{dir}}$  is longer than  $22 \log \log n$ .
4. No vertex of  $D_b$  lies on more than  $240(\log \log n)^2$  paths.

The set of start vertices of the walks in  $\mathcal{W}^\rightarrow$  is denoted  $S_{CB}^\rightarrow$  and the set of terminal vertices of the walks in  $\mathcal{W}^\leftarrow$  is denoted  $S_{CB}^\leftarrow$ . Clearly,  $S_{CB}^{\text{dir}} \subseteq V_b \setminus V_a$ . The collection of walks will have the additional property

$$5. |V \setminus (V_a \cup S_{CB}^{\text{dir}})| \leq \frac{n}{(\ln n)^4}.$$

In words, condition 3 says that the paths in  $\mathcal{W}^{\text{dir}}$  are short, condition 4 says that the paths are ‘spread out’ and condition 5 says that very few vertices are left out of the collection.

We emphasize that  $\mathcal{W}^{\text{dir}}$  is constructed without use of any information about  $z$ . Therefore,  $z$  (which was a random vertex to begin with) can be viewed as a vertex chosen uniformly at random *after* the collection  $\mathcal{W}^{\text{dir}}$  is constructed. Heuristically, we can think of  $\mathcal{W}^\rightarrow$  and  $\mathcal{W}^\leftarrow$  as collections of connecting paths that are updated whenever  $\Delta_a$  or  $\Delta_b$  ‘shrink,’ but we only ‘look’ at these collections when we need them.

If  $z \in S_{CB}^{\text{dir}}$  then we connect  $z$  back to  $V_a$  by way of the unique path in  $\mathcal{W}^{\text{dir}}$  that begins at  $z$  (if  $\text{dir} = \rightarrow$ ) or ends at  $z$  (if  $\text{dir} = \leftarrow$ ). If  $z$  does not lie in  $S_{CB}^{\text{dir}}$  we put  $i$  into  $L$  (note that we have either  $z = \tilde{x}_i$  or  $z = \tilde{y}_i$ ). Arc disjoint paths for the pairs  $(\tilde{x}_i, \tilde{y}_i), i \in L$  are found in Phase 2.

A network flow technique for the construction of the collection of paths  $\mathcal{W}^{\text{dir}}$  follows from the proof of Lemma 3, which is given in Section 2.3.3 below.

1. **subroutine** CONNECTBACK( $V_a, z, \text{dir}, z', i, W_{CB}$ )
2. **begin**
3.     **if**  $z \in V_a$
4.         **then**  $z' \leftarrow z$
5.         **else**
6.             **Execute** REMOVE( $\Delta_b$ )
7.             **Construct**  $\mathcal{W}^{\text{dir}}$  (see Lemma 3 for algorithm).
8.             **if**  $z \notin S_{CB}^{\text{dir}}$
9.                 **then**  $L \leftarrow L \cup \{i\}$
10.             **else**
11.                  $W_{CB} \leftarrow$  the unique path in  $\mathcal{W}^{\text{dir}}$  with start/terminal vertex  $z$
12.                  $z' \leftarrow$  terminal/start vertex of  $W_{CB}$
13.                  $\Delta_b \leftarrow \Delta_b \setminus W_{CB}$
14.             **fi**
15.     **fi**
16. **end** CONNECTBACK

## 2.3 Analysis of Phase 1

There are three facts concerning Phase 1 that remain to be shown: that the flow needed in the Initialization exists, that  $V_3$  stays large and that at the end of Phase 1 **whp** we have  $L = O\left(\frac{n}{(\log n)^4}\right)$ .

### 2.3.1 Initialization

In this subsection we show that if (5) holds and  $r$  is sufficiently large then we can find arc-disjoint paths from  $\{x_1, \dots, x_\kappa\}$  to  $\tilde{X}$  in  $D_1$  and arc-disjoint paths from  $\tilde{Y}$  to  $\{y_1, \dots, y_\kappa\}$  in  $D_6$ , for *any* choice of  $x_1, \dots, y_\kappa$  consistent with the premises of Theorem 1, and every choice for  $\tilde{X}, \tilde{Y}$ . We assume that we have

$$8\alpha > \epsilon_2 > r^{-1} \quad (9)$$

For  $S \subseteq V$ , let

$$\alpha(S) = \sum_{v \in S} |\{i : x_i = v\}| \quad \text{and} \quad \xi(S) = |S \cap \tilde{X}|.$$

It follows from a theorem of Gale [12] (see Bondy and Murty [3] Theorem 11.8) that if

$$d_{D_1}^+(S) \geq \xi(\bar{S}) - \alpha(\bar{S}), \quad \forall S \subseteq V. \quad (10)$$

then there exists a flow in the network defined on  $D_1$  such that exactly one unit of flow travels through each vertex in  $\tilde{X}$  and the amount of flow traveling through each vertex  $v \in \{x_1, \dots, x_\kappa\}$  is  $|\{i : x_i = v\}|$ . In other words, (10) implies a successful run of Phase 2.

Now, if  $|S| \leq n/2$  then, applying (4), (5) and (9), we have

$$d_{D_1}^+(S) \geq |S|\Phi_1 \geq |S|\beta_0 r \geq 8\alpha r|S| \geq \epsilon_2 r|S| \geq \alpha(S) - \xi(S) = \xi(\bar{S}) - \alpha(\bar{S}).$$

On the other hand, if  $|S| > n/2$  then we have

$$d_{D_1}^+(S) = d_{D_1}^-(\bar{S}) \geq |\bar{S}|\Phi_1 \geq |\bar{S}|\beta_0 r \geq \epsilon_2 r|\bar{S}| \geq \xi(\bar{S}) - \alpha(\bar{S}).$$

Therefore, Phase 1 succeeds with respect to  $X, \tilde{X}$ . The same argument applies to  $Y, \tilde{Y}$ . To ensure these paths are of length  $O(\log n)$  we can solve a minimum cost maximum flow problem as indicated in Kleinberg and Rubinfeld [13].

### 2.3.2 On the size of $V_a$

**Lemma 2** *Throughout GENPATHS we have*

$$|V_a| \geq (1 - \gamma_0)n$$

where

$$\gamma_0 = \frac{\beta_0 \gamma}{10}.$$

**Proof:** It follows from (8) that  $\Delta_a$  is a  $(\beta_0 r/2)$ -expander throughout the execution of Phase 1. It follows from Lemma 1 that the diameter of  $\Delta_a$  is always at most

$$\tau = \left\lceil 2 \log_3 n + \frac{2}{\alpha \gamma} \right\rceil. \quad (11)$$

Indeed, consider breadth first search from some  $v \in V_a$ . Let  $L_t, t \geq 0$  be the vertices at distance  $t$  from  $v$ . Lemma 1 implies that the cardinalities of the  $L_t$  grow at a rate at least 3 until they reach size  $(2\gamma\alpha/\beta_0)n$ . The same will be true for breadth first search to a target vertex  $w$ . This accounts for the first term in (11). Once we have  $L_t$  reaches  $(2\gamma\alpha/\beta_0)n$  we use that fact that going to the next level involves finding  $\beta_0 r |L_t|/2$  “new arcs”, at least until the size  $n/2$  is reached. This accounts for the second term in (11).

Thus the total number of arcs in the paths that are removed from  $D_a$  is at most  $\kappa\tau$ . Let  $B$  be the set of vertices that are removed from  $\Delta_a$  in the course of Phase 1, and let  $B_1$  be the set of vertices in  $B$  incident with at least  $\beta_0 r/4$  of the paths that are generated in  $D_a$ . We have

$$|B_1| \leq \frac{4\kappa\tau}{\beta_0 r} \leq \frac{\gamma_0 n}{2}$$

provided

$$\epsilon_1 \leq \frac{\beta_0^2 \gamma}{160}. \quad (12)$$

where  $\epsilon_1$  is as in the statement of Theorem 1. Let  $B_2 = B \setminus B_1$  (i.e. those vertices removed from  $\Delta_a$  that lie on less than  $\beta_0 r/4$  of the paths generated in  $D_a$ ).

Assume for the sake of contradiction that  $|B_2| > |B_1|$ . Let  $B_3$  be the *first*  $|B_1|$  vertices of  $B_2$  to join  $B$ . Note that the vertices in  $B_3$  have a large degree to  $B_1 \cup B_3$  (otherwise these vertices would remain in  $V_a$ ). Applying (4) we have

$$in_{D_a}(B_1 \cup B_3) \geq \frac{\beta_0 r}{4} |B_3| = \frac{\beta_0 r}{8} |B_1 \cup B_3| > \alpha r |B_1 \cup B_3|.$$

This contradicts (1).

Therefore,  $|B| = |B_1| + |B_2| \leq 2|B_1| \leq \gamma_0 n$ .  $\square$

### 2.3.3 Analysis of CONNECTBACK

Of course, the first order of business here is to show how the collection of paths  $\mathcal{W}^{\text{dir}}$  is generated.

**Lemma 3** *Suppose that  $D = (V, A)$  is an  $(\alpha, \beta, \gamma)$ -expander and that  $D' = (V', A')$  is a sub-digraph of  $D$  of expansion at least  $\theta r$  where  $\theta > 6\alpha$ . Suppose that  $S \subseteq V'$  and that  $|S| \geq (1 - \frac{\gamma\alpha}{\theta})n$  and let  $T = V' \setminus S$ . Then there exists  $T^* \subseteq T$ , such that  $D'$  contains a collection of walks  $\mathcal{W}^{\text{dir}} = \{W_v : v \in T^*\}$  such that*

1. for  $\text{dir} = \rightarrow / \leftarrow$ ,  $v$  is the start/terminal vertex of  $W_v$  for all  $v \in T^*$ ,
2. the terminal/start vertex of each  $W_v$  is in  $S$ ,
3. each  $W_v$  is of length at most  $22 \log \log n$ ,
4. no vertex of  $D'$  lies on more than  $240(\log \log n)^2$  paths, and

$$5. |T \setminus T^*| \leq \frac{n}{(\log n)^4}.$$

**Proof:** Assume without loss of generality that  $\text{dir} \Rightarrow$ . For  $i = 1, 2, \dots$  let

$$T_i = \{v \in T : \text{dist}_{D'}(v, S) = i\},$$

and set  $T_0 = S$ . Since  $N_{D'}^+(\cup_{k \geq i} T_k) \subseteq T_{i-1}$ , it follows from Lemma 1 that we have

$$|T_{i-1}| \geq \zeta |T_i| \quad \text{for } i \geq 1, \quad (13)$$

where  $\zeta = \frac{\theta - \alpha}{\alpha} > 5$ . Setting  $i_0 = \lceil 11 \log \log n \rceil$  and  $\hat{T} = \bigcup_{i \geq i_0} T_i$  It follows from (13) that we have

$$|\hat{T}| \leq \frac{n}{2(\log n)^4}. \quad (14)$$

Fix  $1 \leq i < i_0$ . We define a flow network  $\mathcal{N}_i$ . The vertex set of  $\mathcal{N}_i$  is  $\{s, t\} \cup \bigcup_{j=1}^{j_0} (C_j \cup C'_j)$  where  $C_1$  and  $C'_1$  are disjoint copies of  $T_i$ , for  $2 \leq j \leq i$ ,  $C_j$  and  $C'_j$  are disjoint copies of  $\bigcup_{\ell \geq i+1-j} T_\ell$  and, for  $i < j \leq j_0 = 2i_0$ ,  $C_j$  and  $C'_j$  are disjoint copies of  $V'$ . The vertices  $s$  and  $t$  will be the source and sink, respectively, for the flow we introduce to  $\mathcal{N}_i$ . A vertex  $v$  in  $V'$  may appear many times in the vertex set of  $\mathcal{N}_i$ ; a copy of  $v$  in  $C_j$  is denoted  $v_j$ , and a copy of  $v$  in  $C'_j$  is denoted  $v'_j$ . For ease of notation, we let  $\phi$  be the map that takes the vertices of  $\mathcal{N}_i$  to their corresponding vertices in  $V'$ . The arc-set of  $\mathcal{N}_i$  is defined as follows. There is an arc from  $s$  to each vertex of  $C_1$ . Each  $v \in S$  gives rise to arcs  $(v'_j, t)$ ,  $i < j \leq j_0$ . If  $v'_j \in C'_j$  and  $w_{j+1} \in C_{j+1}$  are such that  $(v, w)$  is an arc of  $D'$  then  $(v'_j, w_{j+1})$  is an arc of  $\mathcal{N}_i$ . All arcs described so far have infinite capacity. In addition there are arcs  $(v_j, v'_j)$  of unit capacity defining a perfect matching between  $C_j$  and  $C'_j$  for  $1 \leq j \leq j_0$ .

**Claim 1**  $\mathcal{N}_i$  contains an  $s - t$  flow of value at least  $|T_i| - \frac{n}{(\log n)^5}$ .

We first show the Lemma follows from Claim 1. The flow given by Claim 1 defines paths in  $D'$  from all but at most  $\frac{n}{(\log n)^5}$  vertices of  $T_i$  to  $S$ , each of length at most  $j_0$ . No vertex of  $V'$  can be on more than  $j_0$  paths since each visit to  $v$  uses a  $(v_j, v'_j)$  arc for some  $j$ . Repeating this construction for  $i = 1, 2, \dots, i_0$  we find paths for all but a set  $\tilde{T}$  of at most  $i_0 \frac{n}{(\log n)^5} \leq \frac{n}{2(\log n)^4}$  vertices and no vertex can be on more than  $i_0 j_0$  paths. Putting  $T^* = T \setminus (\hat{T} \cup \tilde{T})$  and using (14) gives us the lemma.

It only remains to prove Claim 1. Of course, we do this via the max-flow min-cut theorem. Consider a cut  $Z \dot{\cup} \bar{Z}$  of  $\mathcal{N}_i$  where the vertex set  $Z$  contains  $s$  but not  $t$ . Let  $A_j = Z \cap C_j$ ,  $B_j = C_j \setminus A_j$ ,  $A'_j = Z \cap C'_j$  and  $B'_j = C'_j \setminus A'_j$  for  $j = 1, 2, \dots, j_0$ . Assume for the sake of contradiction that the capacity of this cut is less than  $|C_1| - \frac{n}{(\log n)^5}$ . It follows from this assumption that the cut contains no infinite capacity arcs and therefore

$$A_1 = C_1, \quad \phi(A_{j+1}) \supseteq N_{D'}^+(\phi(A'_j)) \text{ for all } j, \quad \text{and} \quad \phi(A'_j) \cap S = \emptyset \text{ for all } j. \quad (15)$$

The capacity of the cut is

$$|B'_1| + \sum_{j=2}^{j_0} |\phi(A_j) \cap \phi(B'_j)|. \quad (16)$$

The third condition of (15) implies that for all  $j$ ,  $|A'_j| < \frac{\gamma\alpha}{\theta}n$ . It then follows from Lemma 1 and the second condition of (15) that we have  $|A_{j+1}| \geq \zeta|A'_j|$ . This implies that for all  $j$  we have either

$$|A'_{j+1}| \geq \frac{1}{2}|A_{j+1}| \geq \frac{\zeta}{2}|A'_j| \quad (17)$$

or

$$|\phi(A_{j+1}) \cap \phi(B'_{j+1})| \geq \frac{1}{2}|A_{j+1}| \geq \frac{\zeta}{2}|A'_j|. \quad (18)$$

Now, if  $|A'_1| \leq \frac{n}{(\log n)^5}$  then  $|B'_1| \geq |C_1| - \frac{n}{(\log n)^5}$ , which contradicts our initial assumption. On the other hand, if  $|A'_1| > \frac{n}{(\log n)^5}$  then, since  $(\frac{\zeta}{2})^{j_0-1} > (\log n)^5$ , condition (17) cannot always hold. Let  $j_1 \geq 1$  be the first  $j$  for which (18) holds. We have

$$|\phi(A_{j_1+1}) \cap \phi(B'_{j_1+1})| \geq (\zeta/2)^{j_1}|A'_1| \geq |A'_1|.$$

The capacity of the cut is at least  $|B'_1| + |A'_1| = |C_1|$ . This is a contradiction.  $\square$

To get the collection of paths needed for `CONNECTBACK` we apply Lemma 3 with  $D' = \Delta_b, V' = V_b, S = V_a \cap V_b$ . So, for example, we have  $S_{CB}^{\text{dir}} = T^*$ . It remains to show that **whp** we have  $|L| \leq \frac{n}{(\log n)^4}$ .

Note that Lemma 3 can only be applied if  $V_a \cap V_b$  is large. However, by applying the proof of Lemma 2 and the fact that the paths generated by `CONNECTBACK` are short (length at most  $22 \log \log n$ ) we see that  $|V_b| = n - O(n \log \log n / \log n)$  throughout and this is sufficient (furthermore, the assumption that  $\theta > 6\alpha$  in Lemma 3 is justified since it follows from this observation that the expansion of  $\Delta_b$  is always at least  $3\beta_0 r/4$ ). However, we shall see that  $V_b$  is **whp** larger than this. This is where we use the fact that the paths in  $\mathcal{W}^{\text{dir}}$  are spread out (i.e. the fact that there are at most  $240(\log \log n)^2$  paths in  $\mathcal{W}^{\text{dir}}$  through any one vertex).

It follows from this fact that the probability that that an arbitrary vertex  $w$  is on the path  $W_i^{CB\text{dir}}$  at most  $240(\log \log n)^2/n$ . It follows that we have

$$\begin{aligned} \Pr\left(\left|\{i : w \in W_i^{CB\rightarrow}\}\right| + \left|\{i : w \in W_i^{CB\leftarrow}\}\right| \geq 20\right) &\leq \Pr(B(2\kappa, 240(\log \log n)^2/n) \geq 20) \\ &\leq \binom{2\kappa}{20} \left(\frac{240(\log \log n)^2}{n}\right)^{20} \\ &= o((\log n)^{-19}). \end{aligned} \quad (19)$$

Let  $B$  be the set of vertices which are removed from  $\Delta_b$  by applications of **REMOVE**. Let  $X_1$  be the set of vertices in  $B$  that are on at least 20 of the paths  $W_i^{CB\rightarrow}, W_i^{CB\leftarrow}$ . Note that  $X_1$  contains the set  $B_1$  introduced in the proof of Lemma 2 ( $B_1$  is the collection of vertices taken out of  $V_b$  by **REMOVE** that are on many of the paths). It follows from (19) and Markov's inequality that **whp** we have  $|X_1| \leq n/(\log n)^{18}$ . Now,  $B$  (which contains  $V \setminus V_b$  at every step) consists of  $B_1$  together with extra vertices deleted by **REMOVE**. In total this will be at most  $2|B_1|$  vertices removed by the argument of Lemma 2, following (12). Thus,  $|B| \leq 2|B_1| \leq 2|X_1|$ . Therefore

$$|B| \leq \frac{n}{(\log n)^{18}} \quad (20)$$

**whp**.

Now, a failure (i.e. the index  $i$  joining the set  $L$ ) can occur in one of two ways. On one hand we have a failure if either  $v_i$  or  $u_i$  does not lie in  $V_a \cup V_b$ , and on the other hand a failure results when  $u_i \in V_b \setminus (V_a \cup S_{CB}^{\rightarrow})$  or  $v_i \in V_b \setminus (V_a \cup S_{CB}^{\leftarrow})$ . It follows from (20) that the total number of failures of the first type is **whp** at most  $\frac{n}{(\log n)^{18}}$ . For failures of the second type we note that  $v_1, \dots, v_\kappa$  form a random sequence of size  $o(n)$ . The probability that a particular vertex gives a failure of the second kind is at most

$$\frac{|S_{CB}^{\text{dir}}|}{n} = O\left(\frac{1}{(\log n)^4}\right).$$

Applying the Chernoff bound for the tails of the binomial, we see that, **whp** the total number of failures of the second kind is  $O(n/(\log n)^4)$ .

**Remark 4** *Suppose  $D$  has the following vertex expansion property for small sets:  $S \subseteq V$ ,  $|S| \leq \frac{2}{r}n$  implies that  $|N_D^*(S)| \geq (1 - \alpha)r|S|$ . The algorithm of Theorem 4 can be modified to split  $D$  so that each subgraph  $D_i$  and small  $S$  satisfies  $|N_{D_i}^*(S)| \geq \frac{1-30\alpha}{13}r|S|$ . Then the shortest paths in  $\Delta_a$  will be of length  $O(\log_r n)$  and the claim in Remark 2 will follow.*

## 2.4 Phase 2.

The set of pairs  $\{(\tilde{x}_i, \tilde{y}_i) : i \in L\}$  have not yet been connected by paths. We have seen that **whp** the number of such pairs,  $|L|$ , is at most  $O(n/(\log n)^4)$ . These pairs are dealt with by the algorithm described below which uses digraphs  $D_7 - D_{13}$ .

The heart of the algorithm is a randomized method (based on a multicommodity flow result of Leighton and Rao [16]) for connecting pairs of vertices with arc disjoint paths which works **whp** when the collection of pairs is generated uniformly at random. So, as in Phase 1, some preliminary steps must be taken in order to reduce the problem of connecting an arbitrary set of pairs of vertices with arc-disjoint paths to the problem of connecting a random collection of pairs with arc-disjoint paths. We proceed directly to a description of the algorithm. Let  $m = |L|$  and  $\lambda = \lceil \log n \rceil$ .

We begin by ‘amplifying’ each start vertex  $\tilde{x}_i, i \in L$  and each end vertex  $\tilde{y}_i, i \in L$  to a collection of  $\lambda$  vertices. This process occurs in steps **(a)** and **(b)**.

- (a) In this step, we choose a collection of vertices  $w_j, 1 \leq j \leq 2m$ , and a collection of sets of vertices  $W_j, 1 \leq j \leq 2m$ , such that for  $1 \leq j \leq 2m$ ,
- (i)  $w_j \in W_j$ ,
  - (ii)  $|W_j| = \lambda$ ,
  - (iii) The sets  $W_j$  are pairwise disjoint, and
  - (iv)  $D_9$  contains an arborescence with vertex set  $W_j$  and root  $w_j$ . For  $1 \leq j \leq m$  this arborescence is directed away from the root and for  $m + 1 \leq j \leq 2m$  this arborescence is directed toward the root.

Following [17], we find these arborescences by partitioning large arborescences of  $D_9$ . We begin with a rooted spanning arborescence  $T$  with the property that all arcs are directed away from the root. We generate  $W_1, \dots, W_m$  greedily from  $D_9$ , removing an arborescence from  $T$  once it is used. Of course, this process will divide  $T$  into a number of components. However, since the maximum degree of  $D_9$  is  $r$ , the number of components produced in this process is at most  $r\lambda m = O\left(\frac{nr}{(\log n)^3}\right)$ . Since any tree having at least  $\lambda$  vertices contains a subtree having exactly  $\lambda$  vertices, we will always be able to find the needed arborescences. We then apply REMOVE to  $D_9$  less the vertex set  $\cup_{i=1}^m W_i$  to produce an expander  $D'_9$ . It follows from the proof of Lemma 2 that  $D'_9$  has  $n - o(n)$  vertices. We repeat the process described above (this time using  $D'_9$  and an arborescence directed towards the roots) to produce  $W_{m+1}, \dots, W_{2m}$ .

- (b) Let  $S_X = \{\tilde{x}_i : i \in L\}$  and  $S_Y = \{\tilde{y}_i : i \in L\}$  denote the sets of vertices that need to be joined. Use a network flow algorithm (analogous to what is given in the Initialization step of Phase 1) in  $D_7$  to connect in an arbitrary manner the vertices of  $S_X$  to  $W_X = \{w_1, \dots, w_m\}$  by  $m$  arc disjoint paths. Using the same network flow algorithm in  $D_8$ , connect in an arbitrary manner the vertices of  $W_Y = \{w_{m+1}, \dots, w_{2m}\}$  to  $S_Y$  by  $m$  arc disjoint paths. The expansion properties of  $D_7$  and  $D_8$  ensure that such paths always exist (as we saw in the Initialization step of Phase 1).

Let  $\hat{x}_k$  (resp.  $\hat{y}_k$ ) denote the vertex in  $W_X$  that was connected to the end-point  $\tilde{x}_k$  (resp.  $\tilde{y}_k$ ). Our problem is now to find arc-disjoint paths joining  $\hat{x}_k$  to  $\hat{y}_k$  for  $1 \leq k \leq m$ . If  $w_t$  has been renamed as  $\hat{x}_k$  (resp.  $\hat{y}_k$ ) then rename the elements of  $W_t$  as  $\hat{x}_{k,\ell}$ , (resp.  $\hat{y}_{k,\ell}$ )  $1 \leq \ell \leq \lambda$ .

- (c) Choose  $\xi_j, 1 \leq j \leq \lambda m$ , and  $\eta_j, 1 \leq j \leq \lambda m$ , uniformly at random from  $V$  without replacement. Using a network flow algorithm (as in (b)) connect  $\{\hat{x}_{k,\ell} : 1 \leq k \leq m, 1 \leq \ell \leq \lambda\}$  to  $\{\xi_j : 1 \leq j \leq \lambda m\}$  by arc-disjoint paths in  $D_{10}$ . Similarly, connect  $\{\eta_j : 1 \leq j \leq \lambda m\}$  to  $\{\hat{y}_{k,\ell} : 1 \leq k \leq m, 1 \leq \ell \leq \lambda\}$  by arc-disjoint paths in  $D_{13}$ . Rename the other endpoint of the path starting at  $\hat{x}_{k,\ell}$  (resp. ending at  $\hat{y}_{k,\ell}$ ) as  $x_{k,\ell}^*$  (resp.  $y_{k,\ell}^*$ ).
- (d) Choose  $z_{k,\ell}^*, 1 \leq k \leq m, 1 \leq \ell \leq \lambda$  uniformly at random from  $V$  with replacement. (We sample without replacement in (c) to ensure that all vertices have demands 0

or 1 in the flow algorithm. Here it is convenient to sample with replacement so that these choices are independent.) Now, it is important to note that the pairs  $x_{k,\ell}^*, z_{k,\ell}^*$  and the pairs  $z_{k,\ell}^*, y_{k,\ell}^*$  are (when viewed separately) perfectly random. We are using the same ‘trick’ that we used in Phase 1 for replacing the problem of connecting arbitrary pairs to the problem of connecting random pairs.

The paths between pairs of the form  $x_{k,\ell}^*, z_{k,\ell}^*$  and between pairs of the form  $z_{k,\ell}^*, y_{k,\ell}^*$  are generated at random. Using the multicommodity flow algorithm of Leighton and Rao [16], find a collection of paths  $P_{u,v;\theta}$ ,  $u \neq v \in V, 1 \leq \theta \leq \nu_{u,v}$  where each  $P_{u,v;\theta}$  is a path in  $D_{11}$  from  $u$  to  $v$ . These are the flow paths given by Theorem 18 in [16] ( $\nu_{u,v}$  is simply the number of flow paths we have for the pairs  $u, v$ ). Let  $\mathcal{P}_{u,v} = \{P_{u,v;\theta} : 1 \leq \theta \leq \nu_{u,v}\}$ . For each  $P_{u,v;\theta}$  we will have a flow value  $f_{u,v;\theta} > 0$  and we let  $F_{u,v} = \sum_{\theta=1}^{\nu_{u,v}} f_{u,v;\theta}$ . Theorem 18 promises:

(P1) For all arcs  $e$  of  $D_{11}$ ,

$$\sum_{(u,v,\theta): e \in P_{u,v;\theta}} f_{u,v;\theta} \leq 1.$$

(P2)

$$F_{u,v} \geq \frac{c_2}{n \log n}$$

for some absolute constant  $c_2 > 0$ .

(P3) The length of each path  $P_{u,v;\theta}$  is at most  $\lambda_1 = c_1 \log_r n$  for some absolute constant  $c_1 > 0$ .

For  $u, v \in V$  let  $P_{u,v}$  be the probability distribution over  $\mathcal{P}_{u,v}$  where  $P_{u,v}(P_{u,v;\theta}) = f(u, v, \theta) / F(u, v)$ . Then for each  $k, \ell$  choose  $W'_{k,\ell}$  randomly from  $\mathcal{P}_{x_{k,\ell}^*, z_{k,\ell}^*}$  using the distribution  $P_{x_{k,\ell}^*, z_{k,\ell}^*}$  to select the path.

Let  $B'_k$  denote the *bundle* of paths  $\{W'_{k,\ell}, 1 \leq \ell \leq \lambda\}$ . Carry out the same construction in  $D_{12}$  and construct a bundle of paths  $B''_k = \{W''_{k,\ell}, 1 \leq \ell \leq \lambda\}$  where  $W''_{k,\ell}$  is a path from  $z_{k,\ell}^*$  to  $y_{k,\ell}^*$ .

Let  $\pi_0 = \max_e \Pr(e \in P)$  where  $P$  is a path chosen by (i) randomly choosing endpoints  $u, v$  and then (ii) choosing  $P \in \mathcal{P}_{u,v}$  according to the distribution  $P_{u,v}$ . We have

$$\pi_0 = \max_e \sum_{P_{u,v;\theta} \ni e} \frac{1}{n^2} \cdot \frac{f(u, v, \theta)}{F(u, v)} \leq \frac{1}{n^2} \frac{n \log n}{c_2} = \frac{\log n}{c_2 n}.$$

We say that  $W'_{k,\ell}$  is *bad* if there exists  $k' \neq k$  such that  $W'_{k,\ell}$  shares an arc with a walk in a bundle  $B'_{k'}$ .

Now, suppose the bundles in the set  $\{B_j : j \neq k\}$  are *fixed*. The collection of paths involved in these bundles gives at most  $m\lambda\lambda_1$  arcs. Thus, the probability that  $W_{k,\ell}$  is bad, conditioning on what happens outside the bundle  $B_k$ , is at most

$$\pi_0 m \lambda \lambda_1 = O\left(\frac{1}{\log n}\right).$$

We say that index  $k$  is bad if either  $B'_k$  or  $B''_k$  contain more than  $\lambda/3$  bad walks. If index  $k$  is not bad then we can find a walk from  $x_{k,\ell}^*$  to  $y_{k,\ell}^*$  through  $x_{k,\ell}^*$  for some  $\ell$  which is arc disjoint from all other walks. This gives a walk

$$x_k - \tilde{x}_k - \hat{x}_k - \hat{x}_{k,\ell} - x_{k,\ell}^* - z_{k,\ell}^* - y_{k,\ell}^* - \hat{y}_{k,\ell} - \hat{y}_k - \tilde{y}_k - y_k,$$

which is arc-disjoint from all other such walks.

The probability that index  $k$  is bad is at most

$$2 \Pr(B(\lambda, O((\log n)^{-1}) \geq \lambda/3) = O(n^{-2}).$$

So with probability 1-o(1) there are no bad indices.

## A Splitting an expander digraph

We prove two results on splitting  $D$  into  $D_1 \cup \dots \cup D_k$  where  $D_i = (V, A_i)$ . One is non-constructive and shows what might be achieved. The second is constructive and uses the first. The split produced by the second is not as good as indicated by the first result. We use a subscript  $i$  to denote graph-theoretic constructs related to  $D_i$ . Thus  $d_i^+(v)$  is the out-degree of  $v$  in  $D_i$ . Left unsubscripted, such things refer to  $D$ . Thus  $d^-(v) = r$ .

In Section B we prove

**Theorem 3** *Let  $k \geq 2$  be a positive integer and let  $\epsilon > 0$  be a small positive real number. Suppose that the  $r$ -regular digraph  $D = (V, A)$  has edge expansion  $\Phi$  and that we have*

$$\frac{r}{\ln r} \geq 7k\epsilon^{-2} \text{ and } \Phi \geq 5\epsilon^{-2}k \ln 2er.$$

*Then there exists a partition  $A = A_1 \cup A_2 \cup \dots \cup A_k$  such that for  $1 \leq i \leq k$*

$$\Phi_i \geq (1 - \epsilon)\frac{\Phi}{k}, \text{ and}$$
$$(1 - \epsilon)\frac{r}{k} \leq \delta^*(D_i) \leq \Delta^*(D_i) \leq (1 + \epsilon)\frac{r}{k}.$$

We then use this in Section C in the proof of

**Theorem 4** *Suppose that the conditions of Theorem 3 hold, and suppose further that  $D$  is an  $(\alpha, \beta, \gamma)$ -expander. Then there is a randomised polynomial time algorithm (running time  $O(n^2 \ln n \ln \delta^{-1})$ ) which with probability at least  $1 - \delta$  constructs  $A_1, A_2, \dots, A_k$  such that*

$$\Phi_i \geq (1 - \epsilon)\frac{\Phi}{k} - (\alpha + \epsilon)r,$$

*for  $i = 1, 2, \dots, k$ .*

Note that this theorem is only useful if  $\Phi \geq cr$  for some  $c$  satisfying  $c \gg \alpha$ . For random  $r$ -regular digraphs we can take  $\gamma$  to be a small constant and  $\alpha = O(\gamma + \frac{1}{\sqrt{r}})$ . Also note that there is not enough time to verify that the algorithm succeeds. Instead, we assume it has and repeat the split if we fail to find the required paths.

## B Existence Result

We prove Theorem 3. We will use the general version of the Lovász Local Lemma. For each  $a \in A$  we randomly choose an integer  $i \in [k]$  and then place  $a$  in  $A_i$ . We must show that there is a positive probability of choosing a partition which satisfies the conditions of the theorem.

We begin with some definitions and preliminary observations. Let  $G = (V, E)$  be the  $2r$ -regular (multi-)graph obtained by ignoring orientation in  $D$ . If  $S \subseteq V$  then  $G[S]$  is the subgraph of  $G$  induced by  $S$ . We say that  $S$  is *connected* if  $G[S]$  is.

**Claim 2** For  $v \in V$  there are at most  $(2er)^{s-1}$  sets  $S$  such that (i)  $v \in S$ , (ii)  $|S| = s$  and (iii)  $S$  is connected.

**Proof of Claim 2** The number of such sets is bounded by the number of distinct  $s$ -vertex trees which are rooted at  $v$ . This in turn is bounded by the number of distinct  $2r$ -ary rooted trees with  $s$  vertices. This is equal to  $\binom{2rs}{s} / ((2r-1)s+1)$ , see Knuth [15].  $\square$

In both this section and the sequel we will use the following Chernoff bounds for the tails of the binomial distribution  $B(n, p)$ :

$$\Pr(B(n, p) \geq (1 + \epsilon)np) \leq e^{-\epsilon^2 np/3} \quad (21)$$

$$\Pr(B(n, p) \leq (1 - \epsilon)np) \leq e^{-\epsilon^2 np/2} \quad (22)$$

where  $0 \leq \epsilon \leq 1$ .

For our application of the Lovász Local Lemma, we define the following *bad* events:

(a) For  $v \in V$ ,  $i \in [k]$  and  $* \in \{+, -\}$ ,  $A_{v,i,*} = A_{\{v\},i,*}$  is the event that

$$d_i^*(v) \notin [(1 - \epsilon)r/k, (1 + \epsilon)r/k].$$

(b) For  $S \subseteq V$ ,  $2 \leq |S| \leq n/2$ ,  $S$  connected,  $i \in [k]$  and  $* \in \{+, -\}$ ,  $A_{S,i,*}$  is the event that

$$|d_i^*(S)| < (1 - \epsilon)|d^*(S)|/k.$$

In showing that  $\Phi_i$  is sufficiently large we can restrict our attention to  $S$  for which  $S$  is connected. Indeed, for  $S \subseteq V$  let  $C_1, C_2, \dots, C_t$  be the components of  $G[S]$ . Then for  $* \in \{+, -\}$ ,

$$\Phi_{S,i}^* \geq \min_{1 \leq s \leq t} \frac{d_i^*(C_s)}{|C_s|}.$$

Using the Chernoff bounds given above we obtain,

$$\Pr(A_{v,i,*}) \leq 2e^{-\epsilon^2 r/(3k)} \leq 2e^{-(7 \ln r)/3} < \frac{1}{r^2}$$

and

$$\Pr(A_{S,i,*}) \leq \exp \left\{ -\frac{\epsilon^2 d^*(S)}{2k} \right\} \leq e^{-2|S| \ln r} = \frac{1}{r^{2|S|}}.$$

Now, for  $S \subseteq V$ ,  $1 \leq |S| \leq n/2$  and  $S$  connected, let

$$x_{S,i,*} = \left( \frac{2}{r^2} \right)^{|S|}.$$

We show that for  $*, \# \in \{+, -\}$ ,

$$\Pr(A_{S,i,*}) < x_{S,i,*} \prod_{(S,i,*) \sim (T,j,\#)} (1 - x_{T,j,\#}), \quad (23)$$

where  $(S, i, *) \sim (T, j, \#)$  denotes adjacency of  $A_{S,i,*}$  and  $A_{T,j,\#}$  in the dependency graph of bad events (i.e. we have  $(S, i, *) \sim (T, j, \#)$  if and only if  $A^*(S) \cap A^\#(T) \neq \emptyset$ ). The theorem then follows from the general version of the local lemma, see for example Alon and Spencer [1].

It follows from Claim 2 that if  $|S| = s$  then there are at most  $ks(2er)^t$  events  $A_{T,j,\#}$  with  $|T| = t$  such that  $(S, i, *) \sim (T, j, \#)$ . Thus, using  $1 - x \geq e^{-2x}$  for  $0 \leq x \leq 1/2$  we have

$$\begin{aligned} x_{S,i,*} \prod_{(S,i,*) \sim (T,j,\#)} (1 - x_{T,j,\#}) &\geq \left(\frac{2}{r^2}\right)^s \prod_{t \geq 1} \left(1 - \left(\frac{2}{r^2}\right)^t\right)^{ks(2er)^t} \\ &\geq \left(\frac{2}{r^2}\right)^s \exp \left\{ -2ks \sum_{t \geq 1} \left(\frac{4e}{r}\right)^t \right\} \\ &= \left(\frac{2}{r^2}\right)^s \exp \left\{ -\frac{8kes}{r - 4e} \right\} \\ &> \frac{1}{r^{2s}}, \end{aligned}$$

since for small values of  $\epsilon$ , the fact that  $r/\ln r \geq 7k\epsilon^{-2}$  implies

$$r > 4e + \frac{8ke}{\ln 2}.$$

Thus (23) holds, proving the theorem.  $\square$

## C Splitting Algorithm

In this section, we prove Theorem 4.

**Idea:** We produce the split in a series of rounds that gives a series of vertex sets  $V = B_1 \supseteq B_2 \supseteq \dots \supseteq B_t$ . In round  $i$  we fix the ‘destination’ of a fixed arc if it has at least one endpoint in  $B_i$  but has no endpoint in  $B_{i+1}$ . This is done in such a way that if  $S \subseteq B_j \setminus B_{j+1}$  then  $d_i^+(S), d_i^-(S)$  are large enough and further that every vertex in  $B_j \setminus B_{j+1}$  has few neighbors in  $B_{j+1}$ . We will see that this latter condition accounts for the  $-(\alpha + 2\epsilon)r$  term in the theorem.

Assume we have  $B \subseteq V$ . Initially,  $B = V$ . We randomly colour the arcs of  $D$  **which**

are incident with  $B$ , with  $k$  colours. Note that if  $s_0 = 5k\epsilon^{-2}\Phi^{-1} \ln n$

$$\begin{aligned} \Pr \left( \exists S \subseteq B, i \in [k] \text{ s.t. } |S| > s_0, S \text{ is connected and } \Phi_{i,S} \leq (1 - \epsilon) \frac{\Phi}{k} \right) \\ \leq 2kn \sum_{s \geq s_0} (2er)^{s-1} e^{-\epsilon^2 s \Phi / (2k)} \leq 4kn(2er)^{s_0} e^{-\epsilon^2 s_0 \Phi / (2k)} = O(kn^{-1/5}). \end{aligned}$$

So, in a sense the large sets, take care of themselves. Now consider the smaller sets. Let

$$X_0 = \left\{ v : \exists S \subseteq B, |S| \leq s_0, S \text{ is connected, } v \in S \text{ and } i \in [k] \text{ s.t. } \Phi_{i,S} \leq (1 - \epsilon) \frac{\Phi}{k} \right\}.$$

$X_0$  can be constructed in  $O(n(er)^{s_0}) = O(n^2)$  time.

$$\mathbf{E}(|X_0|) \leq |B| \sum_{s=1}^{s_0} (2er)^{s-1} e^{-\epsilon^2 s \Phi / (2k)} \leq \frac{|B|}{2er}$$

since  $\Phi \geq 5\epsilon^{-2}k \ln 2er$ .

Therefore by Markov's Inequality,

$$\Pr \left( |X_0| \geq \frac{|B|}{er} \right) \leq \frac{1}{2}.$$

We repeat the above colouring until we find that  $|X_0| \leq \frac{|B|}{er}$ . Now recursively define  $X_j = X_{j-1} \cup \{v_j\}$  where  $d^+(v_j, X_{j-1}) \geq (\alpha + \epsilon)r$  or  $d^-(v_j, X_{j-1}) \geq (\alpha + \epsilon)r$ , if such a  $v_j$  exists. Here we use the strong expansion properties of an  $(\alpha, \beta, \gamma)$ -expander: if  $|S| \leq \gamma n$  implies that  $S$  contains at most

$$(r|S| - d^*(S)) \leq \alpha r|S|$$

arcs. Note that  $X_j$  has at least  $(\alpha + \epsilon)rj$  arcs and at most  $j + \frac{|B|}{er}$  vertices. Thus this process stops before  $j$  reaches  $\frac{\alpha|B|}{\epsilon er}$ , unless  $|X_j|$  exceeds  $\gamma n$  first. However, this latter possibility cannot happen since  $|X_0| + \frac{\alpha|B|}{\epsilon er} \leq (1 + \frac{\alpha}{\epsilon}) \frac{1}{er} |B| \leq \gamma |B| \leq \gamma n$  since  $\gamma, \epsilon > r^{-\frac{1}{2}}, \alpha < 1$  implies  $\gamma > (1 + \frac{\alpha}{\epsilon}) \frac{1}{er}$ .

So if  $X$  denotes  $X_j$  when  $v_{j+1}$  cannot be found, then

$$|X| \leq \gamma |B|.$$

We will repeat the construction with  $B$  replaced by  $X$ . Let  $V = B_1 \supseteq B_2 \supseteq \dots \supseteq B_t$  be the sequence of sets constructed.  $B_t$  will be the first set of size at most  $r^{-1} \ln n$ . Since  $\gamma < \frac{1}{2}$ , we have  $t \leq \log_2 n$ . Thus the expected number of re-colourings needed is at most  $2 \log_2 n$  and is  $\leq 3 \log_2 n$  **whp**. We can “brute force” colour the arcs incident with  $B_t$  so that every subset  $S$  of  $B_t$  satisfies  $\Phi_{i,S} \geq (1 - \epsilon) \frac{\Phi}{k}$ . We use Theorem 3 to justify the success of this. The sequence of sets  $B_1, B_2, \dots, B_t$  satisfies

- $|B_j| \leq \gamma^j n$ .
- $S \subseteq B_j \setminus B_{j+1}$  implies  $\Phi_{i,S} \geq (1 - \epsilon) \frac{\Phi}{k}$ .
- $v \in B_j \setminus B_{j+1}$  implies  $v$  has at most  $(\alpha + \epsilon)r$  out-neighbours and at most  $(\alpha + \epsilon)r$  in-neighbours in  $B_{j+1}$ .

So if  $S \subseteq V$  and  $S_j = S \cap (B_j \setminus B_{j+1})$ ,

$$\begin{aligned}
d_i^*(S) &\geq \sum_{j=1}^{t-1} (d_i^*(S_j) - d_i^*(S_j, B_{j+1})) + d_i^*(S_t) \\
&\geq \sum_{j=1}^{t-1} \left( (1 - \epsilon) \frac{\Phi}{k} - (\alpha + \epsilon)r \right) |S_j| + (1 - \epsilon) \frac{\Phi}{k} |S_t| \\
&\geq \left( (1 - \epsilon) \frac{\Phi}{k} - (\alpha + \epsilon)r \right) |S|.
\end{aligned}$$

□
